Abstract

Periampullary Cancer is the term used for neoplasms arising from the head of pancreas, ampulla of Vater, distal bile duct and periampullary region of duodenum. Of these, the pancreatic adenocarcinoma carries the worst prognosis with majority of mortalities within the first year. The overall 5 year survival is less than 3%. Studies have shown that pancreatic carcinoma has the shortest median survival of 17.1 months of all periampullary carcinomas. With the development of metastasis the median survival tends to reduce to 3 to 6 months. We are reporting a case of metastatic periampullary pancreatic adenocarcinoma that received minimal and interrupted chemotherapy due to poor tolerance and yet managed to survive far beyond the reported median survival.

Keywords: Pancreas, Adenocarcinoma, prognosis, periampullary

Introduction:
Pancreatic Adenocarcinoma is the most frequently occurring periampullary cancer, with an incidence of 9 in 100,000 cancers in US annually [1,2,3]. Obstructive jaundice is the form of presentation in 65-75% of patients while other presenting features may be pain, weight loss, anorexia, elevated liver enzymes, new onset diabetes mellitus or pancreatitis [2]. Tumour Marker Ca 19-9 may be helpful in diagnosis which in 75% cases is raised. Diagnostic imaging includes CT scan, MRI scan, ERCP and EUS which also aids in obtaining tissue for histological diagnosis [2,4].

Treatment options include pancreaticoduodenectomy with intent to cure leading to increase in 5 year survival. Palliative options include palliative surgery, Endoscopic stenting and/or chemotherapy [4]. Locally advanced non metastatic periampullary pancreatic Ca has a median survival of 6-10months [5]. However in metastatic settings, median survival is a mere 3-6 months [5,6].

Gemcitibine is the chemotherapeutic agent of choice in palliative settings which causes a modest but significant improvement in clinical condition and to some extent response and survival [5,6].

In this paper we present a case of an elderly lady diagnosed with metastatic periampullary pancreatic Cancer who received suboptimal chemotherapy and managed to survive for 17 months after diagnosis. The case was chosen due to its unusual course and unexpectedly prolonged survival with minimal chemotherapy in metastatic settings.

Case Report:

A seventy six year old female, known diabetic and hypertensive presented to the gastroenterology clinic in September 2014, with history of fever, weight loss and jaundice over the preceding three months. On examination she was deeply jaundiced and emaciated.

Her initial workup done prior to presentation to the hospital included a CT scan of the abdomen obtained in August 2014, which showed biliary obstruction with suspicion of 4 mm non calcified calculus at the level of ampulla. Her ERCP revealed peri ampullary pancreatic carcinoma and duodenal ulcer. Biopsy was taken which was positive for well differentiated adenocarcinoma (Figure 1).
Figure 1: (4X) Showing a fragment of duodenal mucosa. The overlying epithelium shows ulceration and erosion with a dense inflammatory infiltrate. A tumour is seen infiltrating through the muscularis mucosae into the lamina propria.

Her CT scan was repeated at our hospital which was suggestive of intra and extra hepatic biliary dilatation with dilated pancreatic duct traceable all the way up to the ampulla and presence of pulmonary metastasis making it a stage IV disease (Figure 2). However, EUS was recommended for further assessment.

Figure 2: Baseline CT scan showing lung metastasis (blue arrow).

EUS was done which showed 25 x 16 mm mass at the lower end of the common bile duct/in the periampullary region and a local node of 10mm. Patient was discussed in MDT and recommendations were ERCP with metallic stent insertion followed by chemotherapy Gemcitibine with 25% dose reduction. Patient received two cycles of Gemcitibine but due to fatigue and anorexia her regime was switched to Capecetibine. After receiving one cycle of Capecetibine, she was lost to follow up. Her last visit to the hospital was in December 2014.

The patient resurfaced in October 2015 with fever, itching, and vomiting, obstructive jaundice and raised lipase levels. She was treated on lines of cholangitis and pancreatitis with Intravenous Piptazobactam.

CT scan was repeated for restaging purposes and it showed progression in primary disease and appearance of hepatic metastasis (Figure 3).

Figure 3: CT scan repeated after a year showed the presence of liver metastasis (blue arrows) consistent with disease progression.

Her blocked stent was replaced and she was discharged from the hospital in a stable clinical condition with improving liver function tests. She passed away in December 2015, sixteen months after diagnosis and twelve months of no treatment for primary disease.

Discussion:

Periampullary tumors are defined as those tumours that arise within 2 cm of the major papilla in the duodenum and include pancreatic adenocarcinoma, distal bile duct and periampullary duodenal carcinomas [1,4,7]. Ampullary Carcinomas lie in the region of ampulla of Vater and account for about 0.2
percent of tumours of the gastrointestinal tract and 6 percent of periampullary malignancies [1,7]. Clinically it is important to distinguish between ampullary and periampullary tumours due to the significance it imparts to the prognosis and resectability [1]. Ampullary Carcinomas carry a better prognosis [1,7] with 5 year survival ranging from 34 to 45 percent [1].

Most of the patients with pancreatic adenocarcinoma present at a late stage and carry a poor prognosis [1]. Resectability is possible in only 15 percent of cases which increases the long term survival in almost 25 percent of patients [8]. 95 percent of patients usually die within a year and 5 year survival after a curative surgery is only 5 to 20 percent, thus making pancreatic adenocarcinoma the worst of periampullary cancers [1]. Metastatic periampullary pancreatic malignancy has a much lower median survival of 3 to 6 months [6].

Commonly periampullary pancreatic adenocarcinoma presents with jaundice and abdominal pain. Other nonspecific symptoms are weight loss and anorexia. New onset diabetes mellitus is also one form of presentation [2,8].

Mostly periampullary tumours are adenocarcinomas [4]. Radiological workup for pancreatic malignancy includes a CT scan which usually suggests the diagnosis in 95 percent of the cases. In periampullary tumours endoscopic retrograde cholangiopancreatography is a part of diagnostic workup. It has a therapeutic role as well in case of obstructive symptoms with a stent placement [8]. Endoscopic ultrasound has a role in staging workup by assessing the depth of invasion and involvement of peripancreatic lymph nodes along with obtaining fine needle aspiration and brushings for cytology [4]. Amongst the treatment modalities, surgical resection of periampullary malignancies is the only possible way of improving long term survival however, the resectability rate for pancreatic cancer is as low as 20 percent [1].

Metastatic pancreatic cancer is associated with poor prognosis and low median survival of 3 to 6 months. Treatment of metastatic pancreatic cancer remains a challenge. The standard cytotoxic agent is Gemcitibine. Though response rate is poor but it has shown clinical benefit in improving quality of life [6,9]. Patients treated with Gemcitibine have a median survival of 6.2 months and a 1 year survival of 20 percent [10]. Combinations of Gemcitibine with several other chemotherapeutic agents like Capecetibine, Irinotecan, Cisplatin or Oxaliplatin have been studied in trials and have not shown any major advantage in survival [9,10].

A combination of Gemcitibine and Epidermal growth factor Tyrosine kinase inhibitor Erlotinib has been approved by FDA because of a significant long term survival advantage [10].

Review of literature clearly indicates a very low median survival associated with metastatic pancreatic periampullary malignancy even with chemotherapy. In case of our patient, she received interrupted chemotherapy and yet survived for 16 months after diagnosis and 12 months with no treatment whatsoever which was quite extraordinary. The prognosis for periampullary carcinoma in the resected patient is better than pancreatic adenocarcinoma but in case of metastatic disease, however, the outcome is dismal. This particular case high lights the fact that there are indeed number of patients that might abate the need for cytotoxic chemotherapy and the related side effects. So far, there is/are no prognostic factor/s discovered which can be utilized to tailor treatment to each patient individually.
