Abstract
Biliary stenting has been used since the 1970’s to relieve biliary obstruction for a variety of causes including benign and malignant biliary strictures (1). Migration of stents proximally into the biliary tree or distally into the intestinal tract is relatively uncommon (2). We report a case of a 64 year old female with a peri-ampullary tumour, who had symptomatic obstructive jaundice following ERCP and plastic stent insertion. Follow up imaging showed proximal migration of the plastic stent and blockage of the distal CBD secondary to the peri-ampullary tumour. The biliary stent was safely removed endoscopically using balloon trawl. This case highlights that while biliary stenting for strictures is generally safe and effective, but stent migration to proximal CBD can occur. Balloon trawl is safe and effective way of removing such stents.

Key Words: Common bile duct, biliary stricture, stents, ERCP, peri-ampullary tumour

Case Report:

A 64 year old female patient was seen in outpatient department (OPD) complaining of right upper quadrant pain. She had undergone ERCP and biliary stenting for right upper quadrant pain and jaundice a year previously and then lost to follow up. A biphasic CT scan of the abdomen was performed, which showed a lesion at the ampulla measuring approximately 1.8 cm in size. The previously placed stent was seen to have migrated upwards, into the proximal CBD, above the lesion, resulting in mild intrahepatic biliary dilatation without evidence of pneumobilia. A diagnosis of a proximally migrated CBD stent was made and it was decided to perform an ERCP and stent change. A side-viewing endoscope was passed in standard fashion to the duodenum. The CBD was cannulated over a guide wire and a cholangiogram was performed, which confirmed proximal stent migration (Fig 1).

Fig. 2 Endoscopic image of the ampulla, where the previously placed stent was not visualized.

Fig. 3 Plastic stent removal with a Duralon occlusion balloon.

A Duralon (Wilson-Cook®) occlusion balloon was passed above the stent and inflated to 18 mm, after which the stent was removed by balloon trawl. (Figure 2 & 3).

A repeat cholangiogram was performed, which revealed a dilated biliary tree. A 7cm 7 Fr double pigtail plastic biliary stent was inserted with good biliary drainage. The patient tolerated the procedure well and was discharged home same day.

Discussion:

Biliary stent migration is reported to occur in a minority of patients but its management can be technically difficult for endoscopists (1). Available data suggests that proximal or distal stent migration occurs in 5-10% of patients (2). The risk of stent migration appears to be higher for benign compared to malignant biliary strictures (4). Migrated stents can most often be retrieved using a grasping basket, inflation of a balloon extraction catheter alongside or above the stent, cannulation of the stent, or by grasping it with a rat-tooth forceps (4, 6).

Lahoti et al were able to retrieve these stents in 34 out of 38 patients using a dormia basket or balloon (5). Similarly, Panagiotis et al, were able to retrieve proximally migrated biliary stents in 15 of the 21 patients using balloon trawl in combination with the other techniques (7). While the removal of proximally migrated stents has been well described; this case report further confirms that balloon trawl is safe and effective in the removal of proximally migrated stents and should be considered for these stents.

In summary this is a case of a 64 year old female who underwent ERCP and plastic stent insertion for obstructive jaundice. Follow up imaging after a year showed proximal migration of stent with resulting dilatation. During ERCP, the stent was retrieved by balloon trawl. This case highlights that while biliary stents are very effective in the management of choledocholithiasis, they can migrate and their removal can be challenging for endoscopists. These challenges can be overwhelmed by using various techniques including balloon trawl.
